

# Hand-Eye Calibration Using Dual Quaternions

Konstantinos Daniilidis  
GRASP Laboratory, University of Pennsylvania \*

April 1998

## Abstract

In order to relate measurements made by a sensor mounted on a mechanical link to the robot's coordinate frame we must first estimate the transformation between these two frames. Many algorithms have been proposed for this so called hand-eye calibration but they do not treat the relative position and orientation in a unified way. In this paper we introduce the use of dual quaternions which are the algebraic counterpart of screws. Then we show how a line transformation can be written with the dual quaternion product. We algebraically prove that if we consider the camera and motor transformations as screws then only the line coefficients of the screw axes are relevant regarding the hand-eye calibration. The dual quaternion parameterization facilitates a new simultaneous solution for the hand-eye rotation and translation using the Singular Value Decomposition. Real world performance is assessed directly in the application of hand-eye information for stereo reconstruction as well as in the positioning of cameras. Both real and synthetic experiments show the superiority of the approach over two other proposed methods.

# 1 Introduction

Hand-eye calibration is called the computation of the relative position and orientation between the robot gripper and a camera mounted rigidly on the gripper. This problem concerns also all sensors that are rigidly mounted on mechanical links, like a camera mounted on a binocular head with mechanical degrees of freedom as well as a camera mounted on a vehicle. Although the term sensor-actuator calibration is more appropriate we will throughout this paper use the well-known term “hand-eye”.

The hand-eye transformation is required in a number of sensing-acting tasks. Using a camera mounted on a gripper or a vehicle we can estimate the position of a target to grasp or to reach in camera coordinates. However, the control commands can be expressed only in the coordinate system of the gripper or the vehicle. Even if the desired control criterion is given in camera coordinates we have to know which is the effect of a robot motion in the camera frame.

The second task group is the placement of sensors at desired positions. We can perform stereo by placing a camera mounted on a gripper at multiple poses sharing the same field of view. However, in order to reconstruct the 3D positions we must know the relative orientation from the camera coordinate systems. But the only transformations we know are in the robot coordinates. The same applies for mounting cameras on binocular heads. As the cameras are manually mounted a hand-eye calibration is necessary in order to align the camera coordinate system with the tilt-vergence link.

The usual way to describe the hand-eye calibration is by means of homogeneous transformation matrices. We denote<sup>1</sup> by  $\mathbf{X}$  the transformation from camera to gripper, by  $\mathbf{A}_i$  the transformation matrix from the camera to the world coordinate system and by  $\mathbf{B}_i$  the transformation matrix from the robot base to the gripper at the  $i$ -th pose. Figure 1 illustrates one of the applications of hand-eye calibration which consists of a camera mounted on a gripper. The camera-world transformation  $\mathbf{A}_i$  is obtained with the extrinsic calibration techniques. The robot base to gripper transformation  $\mathbf{B}_i$  is given by the direct kinematic chain from the joint angle readings. We see that for one pose we have two transformations as unknowns: robot base to world and the camera to gripper  $\mathbf{X}$ . In order to eliminate the base to world transformation we need one motion (two poses) which yields the well known hand-eye equation first formulated in (Shiu & Ahmad, 1989) and (Tsai & Lenz, 1989).

$$\mathbf{A}\mathbf{X} = \mathbf{X}\mathbf{B} \quad (1)$$

where  $\mathbf{A} = \mathbf{A}_2\mathbf{A}_1^{-1}$  and  $\mathbf{B} = \mathbf{B}_2^{-1}\mathbf{B}_1$ . As every homogeneous transformation matrix has the form

$$\begin{pmatrix} \mathbf{R} & \vec{t} \\ 0^T & 1 \end{pmatrix}$$

from (1) follows one matrix and one vector equation

$$\mathbf{R}_A\mathbf{R}_X = \mathbf{R}_X\mathbf{R}_B \quad (2)$$

$$(\mathbf{R}_A - \mathbf{I})\vec{t}_X = \mathbf{R}_X\vec{t}_B - \vec{t}_A \quad (3)$$

The majority of the approaches regards the rotation estimation in (2) decoupled from translation estimation, the latter following the former. At least two rotations containing motions with not

---

<sup>1</sup>We use boldface capitals for matrices  $\mathbf{X}$ , arrowed boldface for 3D-vectors  $\vec{x}$ , boldface for real quaternions  $\mathbf{x}$ , checked normal fonts  $\tilde{x}$  for dual scalars, checked arrowed boldface for dual vectors  $\vec{\tilde{x}}$ , and checked boldface for dual quaternions  $\tilde{\mathbf{x}}$ . The natural inner product of two vectors or quaternions is denoted by  $\mathbf{x}^T\mathbf{y}$  and the cross product between 3D-vectors by  $\vec{x} \times \vec{y}$ .

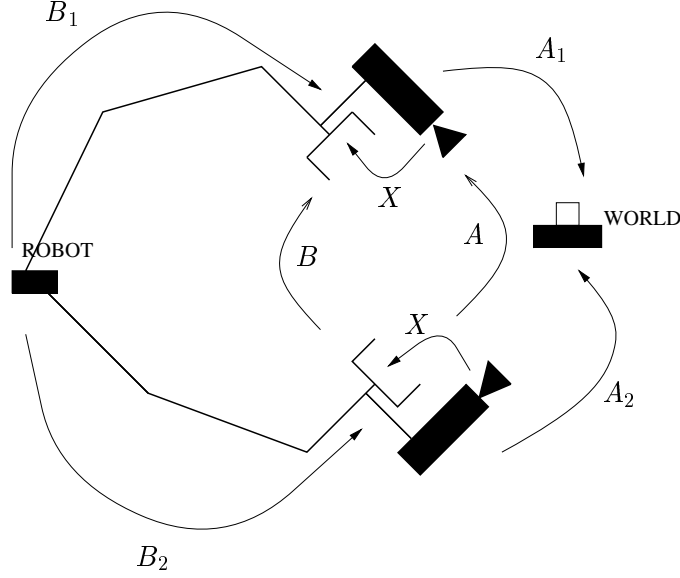

Figure 1: The transformations between different frames at pose 1 and pose 2.

parallel rotation axes are required to solve the problem (Tsai & Lenz, 1989). Several approaches have been proposed for the estimation of  $\mathbf{R}_X$  from (2): using rotation axis and angle (Tsai & Lenz, 1989; Shiu & Ahmad, 1989), quaternions (Chou & Kamel, 1991), and canonical matrix representation (Li & Betsis, 1995) - a survey can be found in (Wang, 1992).

(Horaud & Dornaika, 1995) emphasize the fact that the computation of the extrinsic calibration matrices  $\mathbf{A}_i$  given the projection matrices  $\mathbf{M}_i$  from world to pixel coordinates is an unstable problem. Therefore, they propose the following alternative: Assume that the matrix of intrinsic parameters  $\mathbf{C}$  remains constant during motion. Then the projection matrix reads

$$\mathbf{M}_i = \mathbf{C}\mathbf{A}_i = \begin{pmatrix} \mathbf{C}\mathbf{R}_{A_i} & \mathbf{C}\vec{\mathbf{t}}_{A_i} \end{pmatrix}. \quad (4)$$

We introduce  $\mathbf{N}_i = \mathbf{C}\mathbf{R}_{A_i}$  and  $\vec{\mathbf{n}}_i = \mathbf{C}\vec{\mathbf{t}}_{A_i}$ . Let us assume that one extrinsic calibration  $\mathbf{A}_1$  is known and replace  $\mathbf{X} = \mathbf{A}_1\mathbf{Y}$ , the unknown is now the world-gripper transformation  $\mathbf{Y}$ . Equation (1) can be rewritten as

$$\mathbf{A}_2\mathbf{Y} = \mathbf{A}_1\mathbf{Y}\mathbf{B} \quad \text{or} \quad \mathbf{A}_1^{-1}\mathbf{A}_2\mathbf{Y} = \mathbf{Y}\mathbf{B} \quad (5)$$

which is just a new homogeneous transform equation. However, if we write  $\mathbf{A}_1^{-1}\mathbf{A}_2$  as a function of the projection parameters we find out that  $\mathbf{A}_1^{-1}\mathbf{A}_2$  is independent of the intrinsic parameters  $\mathbf{C}$ :

$$\mathbf{A}_1^{-1}\mathbf{A}_2 = \begin{pmatrix} \mathbf{N}_1^{-1}\mathbf{N}_2 & \mathbf{N}_1^{-1}(\vec{\mathbf{n}}_2 - \vec{\mathbf{n}}_1) \\ 0^T & 1 \end{pmatrix}. \quad (6)$$

Hence, with an appropriate change of the unknown we obtain (5) which can be solved by all the methods solving (1) as well as the one proposed later in this paper.

(Horaud & Dornaika, 1995) are the first who applied a simultaneous non-linear minimization with respect to the rotation quaternion and the translation vector. However, the first simultaneous consideration of rotation and translation in a geometric way was presented by (Chen, 1991) who first introduced the screw theory in the hand-eye calibration.

In this paper we introduce the algebraic entity for a screw: the unit dual quaternion. Dual quaternions are an extension of the real quaternions by means of the dual numbers (Study, 1891;

Blaschke, 1960) and were first introduced by (Clifford, 1873). Dual numbers and dual quaternions have been earlier used in robotics (Walker, 1988; Gu & Luh, 1987; Funda & Paul, 1990) and in computer vision (Walker, Shao, & Volz, 1991; Phong, Horaud, Yassine, , & Pham, 1993). Based on the dual quaternions we prove that

1. the hand-eye transformation is independent of the angle and the pitch of the camera and hand motions and depends only on the line parameters of their screw axes - a result geometrically proved in (Chen, 1991)
2. the unknown screw parameters including both rotation and translation can be simultaneously recovered using the Singular Value Decomposition.

This is the first algorithm in the literature solving simultaneously for rotation and translation without nonlinear minimization. The algorithm was implemented and compared with a two-step algorithm which separately solves for  $\mathbf{R}$  and  $\mathbf{t}$  showing its superior performance. The performance with real data is tested directly in an application. We judge the quality of the obtained hand-eye information on the task of stereo reconstruction using the motor encoders readings of an active camera.

The next section gives an exposition on the properties of dual numbers and dual quaternions. Then, we describe how a line transformation is expressed with dual quaternions and how we obtain a dual quaternion from the  $(\mathbf{R}, \mathbf{t})$ -representation. The dual quaternion is given as a function of the screw parameters and then we prove the independence result. We describe our solution via SVD. and end with experimental results.

## 2 Dual Quaternions

This section outlines briefly the dual quaternions. First quaternions are explained followed by a short description of dual numbers. Finally, the dual quaternions and their relevant properties are introduced.

### Quaternions

Quaternions, invented by Hamilton (Blaschke, 1960) are an extension of the complex numbers to  $\mathcal{R}^4$ . Among other formalisms one definition of quaternions is as pairs  $(s, \vec{q})$  where  $s \in \mathcal{R}$  and  $\vec{q} \in \mathcal{R}^3$ . The following operations

$$\mathbf{q}_1 + \mathbf{q}_2 = (s_1 + s_2, \vec{q}_1 + \vec{q}_2) \quad (7)$$

$$\lambda(s, \vec{q}) = (\lambda s, \lambda \vec{q}), \quad (8)$$

where  $\lambda \in \mathcal{R}$  make the quaternions a vector space over the reals - we will call  $\mathcal{H}$  - with the zero element  $(0, \mathbf{0})$ . The multiplication between quaternions defined as

$$\mathbf{q}_1 \mathbf{q}_2 = (s_1 s_2 - \vec{q}_1^T \vec{q}_2, s_1 \vec{q}_2 + s_2 \vec{q}_1 + \vec{q}_1 \times \vec{q}_2) \quad (9)$$

has a unit element  $(1, \mathbf{0})$  and is associative but not commutative. Therefore the quaternions are an associative algebra and since they do not contain zero-divisors they are a division algebra. The norm of a quaternion is defined as  $\|\mathbf{q}\| = \mathbf{q} \bar{\mathbf{q}}$  where  $\bar{\mathbf{q}}$  is the conjugate quaternion  $(s, -\vec{q})$ . A subgroup of  $\mathcal{H}$  regarding only the multiplication operation are the unit quaternions with norm equal one. For every rotation (element of  $\text{SO}(3)$ ) about an axis  $\vec{n}$  ( $\|\vec{n}\| = 1$ ) with an angle  $\theta$  a corresponding unit quaternion  $\mathbf{q} = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \vec{n})$  exists that maps a vector  $\vec{x} \in \mathcal{R}^3$  to the vector  $\mathbf{q}(0, \vec{x})\bar{\mathbf{q}}$ .

## Dual Numbers

Dual numbers were invented by (Clifford, 1873) and further developed by (Study, 1891) in the last century. A dual number is defined as

$$\check{z} = a + \epsilon b \quad \text{with} \quad \epsilon^2 = 0 \quad (10)$$

The operations addition and multiplication make them an abelian ring called  $\Delta$  but not a field because only dual numbers with real part not zero possess an inverse element. An important property is associated with the derivatives of functions with dual arguments. Since all powers greater equal two of  $\epsilon$  vanish a Taylor expansion yields always

$$f(a + \epsilon b) = f(a) + \epsilon b f'(a). \quad (11)$$

Dual vectors are defined in  $\Delta^3$  and with the addition and the external multiplication with a dual number make a module over the ring  $\Delta$ . Dual vectors with orthogonal real and dual parts are a representation of lines in  $\mathcal{R}^3$  known as Plücker coordinates. The real part is the direction of the line and the dual part is its moment. The inner product between two such dual vectors is equal to the cosine of a dual angle  $\check{\theta} = \theta + \epsilon d$  which has a nice geometric interpretation:  $\theta$  is the angle between the two space lines and  $d$  is their distance.

## Dual Quaternions

Dual quaternions are defined in a similar way like real quaternions as  $(\check{s}, \check{\vec{q}})$  where  $\check{s}$  a dual number and  $\check{\vec{q}}$  a dual vector. The operations have the same definitions

$$\check{\vec{q}}_1 + \check{\vec{q}}_2 = (\check{s}_1 + \check{s}_2, \check{\vec{q}}_1 + \check{\vec{q}}_2) \quad (12)$$

$$\check{\lambda}(\check{s}, \check{\vec{q}}) = (\check{\lambda}\check{s}, \check{\lambda}\check{\vec{q}}) \quad (13)$$

$$\check{\vec{q}}_1 \check{\vec{q}}_2 = (\check{s}_1 \check{s}_2 - \check{\vec{q}}_1^T \check{\vec{q}}_2, \check{s}_1 \check{\vec{q}}_2 + \check{s}_2 \check{\vec{q}}_1 + \check{\vec{q}}_1 \times \check{\vec{q}}_2). \quad (14)$$

The first two (12) and (13) make the dual quaternions a  $\Delta$ -module. Addition (12) and multiplication (14) make them a non-abelian ring with unit element  $(1, \mathbf{0})$ . All three operations make them an associative algebra. Dual vectors  $\check{\vec{q}}$  can be written as dual quaternions  $(0, \check{\vec{q}})$  and their multiplication possesses the nice property

$$(0, \check{\vec{q}}_1)(0, \check{\vec{q}}_2) = (-\check{\vec{q}}_1^T \check{\vec{q}}_2, \check{\vec{q}}_1 \times \check{\vec{q}}_2). \quad (15)$$

The norm of a dual quaternion is defined as  $\|\check{\vec{q}}\|^2 = \check{\vec{q}} \check{\vec{q}}$  and is a dual number with positive real part. If the norm has a non vanishing real part then the dual quaternion has an inverse  $\check{\vec{q}}^{-1} = \|\check{\vec{q}}\|^{-1} \check{\vec{q}}$ . If the norm is equal one then an inverse element exists and is equal to the conjugate quaternion. If  $\check{\vec{q}} = \vec{q} + \epsilon \vec{q}'$  then the unity condition  $\check{\vec{q}} \check{\vec{q}} = 1$  can be written

$$\vec{q} \vec{q} = 1 \quad \text{and} \quad \vec{q} \vec{q}' + \vec{q}' \vec{q} = 0. \quad (16)$$

As we shall describe in the following unit dual quaternions represent general motions of lines and the expression  $\check{\vec{q}} \check{\vec{x}} \check{\vec{q}}$  valid for rotation of points in case of real quaternions is also true for general motion of lines in case of dual quaternions.

### 3 Line transformations with unit dual quaternions

As already known the rotation of a point  $\vec{p}_b$  to a point  $\vec{p}_a$  can be written by means of a unit quaternion  $q$  as the product  $\vec{p}_a = q\vec{p}_b\bar{q}$ . This form allows the concatenation of rotations to be represented by a simple quaternion product. Unfortunately, no such quaternion representation exists for a general rigid transformation including translation. We will describe in this section that the introduction of dual quaternions allows a rigid transformation rule as simple as the one for pure rotations, however, not for a point but for a line.

A line in space with direction  $\vec{l}$  through a point  $\vec{p}$  can be represented with the 6-tuple  $(\vec{l}, \vec{m})$  where  $\vec{m}$  is called the line moment and is equal to  $\vec{p} \times \vec{l}$ . The line moment is normal to the plane through the line and the origin with magnitude equal to the distance from the line to the origin. The constraints  $\|\vec{l}\| = 1$  and  $\vec{l}^T \vec{m} = 0$  guarantee that the degrees of freedom of an arbitrary line in space are four.

We next give an answer to the following problem:

*A line given by its dual quaternion  $\check{l}_a = l_a + \epsilon m_a$  is transformed with  $(R, \vec{t})$  into a line  $\check{l}_b$ . Show that a unit dual quaternion exists such that  $\check{l}_a = \check{q}\check{l}_b\check{q}$ .*

Applying a rotation  $R$  and a translation  $\vec{t}$  to a line  $(\vec{l}_b, \vec{m}_b)$  we obtain the transformed line  $(\vec{l}_a, \vec{m}_a)$

$$\vec{l}_a = R\vec{l}_b \quad (17)$$

$$\begin{aligned} \vec{m}_a &= \vec{p}_a \times \vec{l}_a = (R\vec{p}_b + \vec{t}) \times R\vec{l}_b \\ &= R(\vec{p}_b \times \vec{l}_b) + \vec{t} \times R\vec{l}_b \\ &= R\vec{m}_b + \vec{t} \times R\vec{l}_b. \end{aligned} \quad (18)$$

We change from vector to quaternion notation which means that the vector  $\vec{l}$  is represented by a quaternion with zero scalar part  $l = (0, \vec{l})$ . The terms containing rotation can be easily written with quaternions. The difficulty with the cross-product is tackled with the identity

$$(0, \vec{t} \times \vec{q}) = \frac{1}{2}(q\vec{t} + t\vec{q}) \quad (19)$$

where  $t$  is the translation quaternion  $(0, \vec{t})$  and  $q$  the rotation quaternion  $(0, \vec{q})$ . Using the identity (19) we obtain

$$\begin{aligned} l_a &= ql_b\bar{q} \\ m_a &= qm_b\bar{q} + \frac{1}{2}(ql_b\bar{q}t + tq\bar{l}_b\bar{q}). \end{aligned} \quad (20)$$

We define a new quaternion  $q' = \frac{1}{2}tq$  and a dual quaternion  $\check{q} = q + \epsilon q'$ . It can be easily shown that (20) is equivalent to

$$l_a + \epsilon m_a = (q + \epsilon q')(l_b + \epsilon m_b)(\bar{q} + \epsilon \bar{q}'). \quad (21)$$

Denoting also the lines by dual quaternions  $\check{l}_a$  and  $\check{l}_b$  we obtain

$$\check{l}_a = \check{q}\check{l}_b\check{q}.$$

This formula resembles to the rotation of points with quaternions.

Lines can thus be rigidly transformed using a single operation (multiplying left and right with the conjugate) in the non-abelian ring of dual quaternions. The norm

$$|\tilde{q}|^2 = \tilde{q}\tilde{q} = q\bar{q} + \epsilon(q\bar{q}' + q'\bar{q}) = q\bar{q} + \epsilon/2(q\bar{q}\bar{t} + t\bar{q}\bar{q}) = 1$$

hence  $\tilde{q}$  is a unit dual quaternion. The above relations give also explicitly the transformation from  $(\mathbf{R}, \bar{\mathbf{t}})$  to  $\mathbf{q} + \epsilon\mathbf{q}'$ . The dual part  $\mathbf{q}' = \frac{1}{2}t\mathbf{q}$  and the quaternion  $\mathbf{q}$  can be obtained from the rotation matrix by finding the axis and the angle of rotation. If  $\tilde{q}$  is a solution then  $-\tilde{q}$  is also a solution. It is sufficient to enforce like in non-dual quaternions that the scalar non-dual part is positive in order to eliminate this ambiguity.

Reversely, the translation  $\mathbf{t}$  can be recovered from the dual quaternion as

$$\mathbf{t} = 2\mathbf{q}'\bar{q}. \quad (22)$$

The unit dual quaternion  $\tilde{q}$  can be written as the concatenation of a pure translational unit dual quaternion and a pure rotational quaternion with dual part equal zero i.e.

$$\tilde{q} = (1, \epsilon \frac{\bar{\mathbf{t}}}{2})\mathbf{q}.$$

## 4 Unit dual quaternions and screws

This section shows that the scalar and the vector part of the dual quaternion have a specific meaning which relates them to the kinematic notion of a screw. According to Chasles' theorem (Chen, 1991) a rigid transformation can be modeled as a rotation *with the same angle* about an axis not through the origin and a translation along this axis. As the screw axis is a line in space it depends on four parameters which together with the rotation angle  $\theta$  and the translation along the axis  $d$  (pitch) constitute the six degrees of freedom of a rigid transformation.

In the following we will solve the problem

*Given a rotation  $\mathbf{R}$  about an axis through the origin and a translation  $\bar{\mathbf{t}}$  compute the pitch  $d$  as well as the screw axis given by its direction and moment pair  $(\bar{\mathbf{l}}, \bar{\mathbf{m}})$ .*

The direction  $\bar{\mathbf{l}}$  is parallel to the rotation axis. The pitch  $d$  is the projection of translation on the rotation axis, therefore equal  $\bar{\mathbf{t}}^T \bar{\mathbf{l}}$ . The not mentioned angle  $\theta$  is the same in both the  $(\mathbf{R}, \bar{\mathbf{t}})$  and the screw representation. In order to recover the moment  $\bar{\mathbf{m}}$  we introduce a point  $\bar{\mathbf{c}}$  on the screw axis being the projection of the origin on the axis (Fig. 2).

The coordinate system is shifted to this point and then transformed. The resulting translation is then  $d\bar{\mathbf{l}} + (I - \mathbf{R})\bar{\mathbf{c}}$ . The so called pitch  $d$  reads  $d = \bar{\mathbf{l}}^T \bar{\mathbf{t}}$ . Using the Rodrigues formula

$$\mathbf{R}\bar{\mathbf{c}} = \bar{\mathbf{c}} + \sin(\theta)\bar{\mathbf{l}} \times \bar{\mathbf{c}} + (1 - \cos \theta)\bar{\mathbf{l}} \times (\bar{\mathbf{l}} \times \bar{\mathbf{c}})$$

and  $\bar{\mathbf{c}}^T \bar{\mathbf{l}} = 0$  it follows that

$$\bar{\mathbf{c}} = \frac{1}{2}(\bar{\mathbf{t}} - (\bar{\mathbf{t}}^T \bar{\mathbf{l}})\bar{\mathbf{l}} + \cot \frac{\theta}{2} \bar{\mathbf{l}} \times \bar{\mathbf{t}}). \quad (23)$$

This point  $\bar{\mathbf{c}}$  and hence the screw axis is not defined if the angle  $\theta$  is either 0 or 180. Otherwise the moment vector reads then

$$\bar{\mathbf{m}} = \bar{\mathbf{c}} \times \bar{\mathbf{l}} = \frac{1}{2}(\bar{\mathbf{t}} \times \bar{\mathbf{l}} + \bar{\mathbf{l}} \times (\bar{\mathbf{t}} \times \bar{\mathbf{l}}) \cot \frac{\theta}{2}). \quad (24)$$

We proceed then with the computation of the corresponding quaternion:

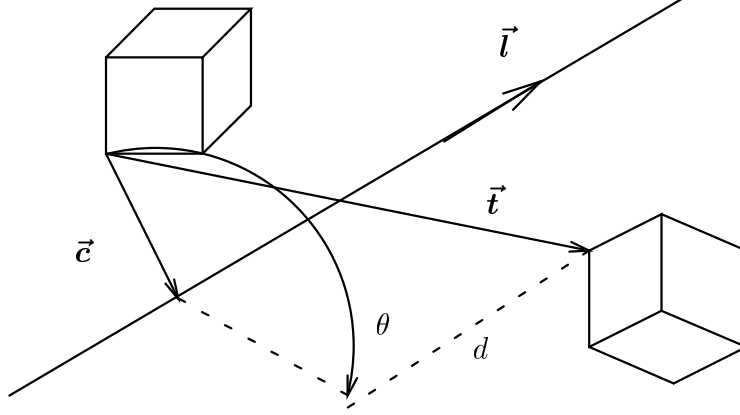

Figure 2: The geometry of a screw: Every motion can be modeled as a rotation with angle  $\theta$  about an axis at  $\vec{c}$  with direction  $\vec{l}$  and a subsequent translation  $d$  along the axis.

Given the screw parameters  $(\theta, d, \vec{l}, \vec{m})$  compute the corresponding dual quaternion  $\tilde{q}$ .

The quaternion derived from the rotation matrix  $\mathbf{R}$  reads

$$(q_0, \vec{q}) = (\cos \frac{\theta}{2}, \sin \frac{\theta}{2} \vec{l}) \quad (25)$$

hence the moment equation (24) can be written

$$\sin \frac{\theta}{2} \vec{m} = \frac{1}{2} (\vec{t} \times \vec{q} + q_0 \vec{t} - \cos \frac{\theta}{2} (\vec{l}^T \vec{t}) \vec{l}).$$

Using  $(\vec{l}^T \vec{t}) = d$  and rewriting

$$\sin \frac{\theta}{2} \vec{m} + \frac{d}{2} \cos \frac{\theta}{2} \vec{l} = \frac{1}{2} (\vec{t} \times \vec{q} + q_0 \vec{t})$$

which is the vector part of the dual part  $\mathbf{q}'$  of the dual quaternion  $\tilde{q}$ . Applying (25) and  $\mathbf{q}' = \frac{1}{2} \mathbf{t} \mathbf{q}$  we obtain

$$\tilde{q} = \begin{pmatrix} q_0 \\ \vec{q} \end{pmatrix} + \epsilon \begin{pmatrix} -\frac{1}{2} \vec{q}^T \vec{t} \\ \frac{1}{2} (q_0 \vec{t} + \vec{t} \times \vec{q}) \end{pmatrix} = \begin{pmatrix} \cos \frac{\theta}{2} \\ \sin \frac{\theta}{2} \vec{l} \end{pmatrix} + \epsilon \begin{pmatrix} -\frac{d}{2} \sin \frac{\theta}{2} \\ \sin \frac{\theta}{2} \vec{m} + \frac{d}{2} \cos \frac{\theta}{2} \vec{l} \end{pmatrix}. \quad (26)$$

Every function  $f$  of dual numbers obeys the rule

$$f(a + \epsilon b) = f(a) + \epsilon b f'(a)$$

hence

$$\cos\left(\frac{\theta + \epsilon d}{2}\right) = \cos \frac{\theta}{2} - \epsilon \frac{d}{2} \sin \frac{\theta}{2} \quad \text{and} \quad \sin\left(\frac{\theta + \epsilon d}{2}\right) = \sin \frac{\theta}{2} + \epsilon \frac{d}{2} \cos \frac{\theta}{2}.$$

It is now straightforward to see that a dual quaternion can also be written as

$$\tilde{q} = \begin{pmatrix} \cos\left(\frac{\theta + \epsilon d}{2}\right) \\ \sin\left(\frac{\theta + \epsilon d}{2}\right) (\vec{l} + \epsilon \vec{m}) \end{pmatrix}. \quad (27)$$

This representation is very powerful since it algebraically separates the angle and pitch information from the line information characterizing the pose of the screw axis. Moreover, writing the dual

angle  $\check{\theta} = \theta + \epsilon d$  and the dual vector  $\check{\vec{t}} = \vec{t} + \epsilon \vec{m}$  (27) becomes equivalent to the pure rotation non-dual equation (25). We can easily verify that

$$\check{q} = (\cos \check{\theta}/2, \check{\vec{t}} \sin \check{\theta}/2)$$

is a unit quaternion  $\check{q}\bar{\check{q}} = 1$ .

## 5 Hand-eye transformation with unit dual quaternions

The concatenation of two rigid displacements or screws can be written as the product of two dual quaternions. Let  $\check{\vec{a}}$  denote the screw of a camera motion and  $\check{\vec{b}}$  denote the screw of the motor motion. Motor (hand) and camera (eye) are rigidly attached to each other. The rigid transformation between them is unknown and it will be denoted by the unit dual quaternion  $\check{q}$ . The screw concatenation yields then

$$\check{\vec{a}} = \check{q}\check{\vec{b}}\bar{\check{q}} \quad (28)$$

which is the most compact equation for the hand-eye relationship since the dual quaternion components are eight and not twelve like in the homogeneous matrices of (1). The scalar part of a dual quaternion  $\check{\vec{a}}$  is  $(\check{\vec{a}} + \bar{\check{\vec{a}}})/2$ , hence

$$Sc(\check{\vec{a}}) = \frac{1}{2}(\check{\vec{a}} + \bar{\check{\vec{a}}}) = \frac{1}{2}(\check{q}\check{\vec{b}}\bar{\check{q}} + \check{q}\bar{\check{\vec{b}}}\bar{\check{q}}) = \frac{1}{2}\check{q}(\check{\vec{b}} + \bar{\check{\vec{b}}})\bar{\check{q}} = \check{q}Sc(\check{\vec{b}})\bar{\check{q}} = Sc(\check{\vec{b}})\check{q}\bar{\check{q}} = Sc(\check{\vec{b}}). \quad (29)$$

According to (27) the scalar parts are equal to the cosine of the respective dual angles:

$$\cos \frac{(\theta_a + \epsilon d_a)}{2} = \cos \frac{(\theta_b + \epsilon d_b)}{2}.$$

which is equivalent to

$$\cos \frac{\theta_a}{2} = \cos \frac{\theta_b}{2} \quad \text{and} \quad d_a \sin \frac{\theta_a}{2} = d_b \sin \frac{\theta_b}{2}.$$

Hence, the angle and the pitch of the motor screw are equal to the angle and the pitch of the camera screw. Hence, the angle and the pitch remain invariant under coordinate transformations. This is also known as the Screw Congruence Theorem (Chen, 1991), its proof without dual unit quaternions is, however, considerably longer than the one line proof in (29).

The fundamental equation  $\check{\vec{a}} = \check{q}\check{\vec{b}}\bar{\check{q}}$  consists of four dual equations. Since the scalar parts are equal only the vector components contribute to the computation of the unknown  $\check{q}$ :

$$\sin \frac{\check{\theta}_a}{2}(0, \check{\vec{a}}) = \check{q}(0, \sin \frac{\check{\theta}_b}{2}\check{\vec{b}})\bar{\check{q}} = \sin \frac{\check{\theta}_b}{2}\check{q}(0, \check{\vec{b}})\bar{\check{q}}.$$

If the angles  $\theta_{a,b}$  are not 0 or 360 degrees the sines can be simplified yielding

$$(0, \check{\vec{a}}) = \check{q}(0, \check{\vec{b}})\bar{\check{q}} \quad (30)$$

which is nothing else then the motion of the lines of the screw axes.

Thus,

1. The hand-eye estimation is independent of the angle and the pitch of the camera and the motor motions.

2. The hand-eye calibration is equivalent to the 3D motion estimation problem from 3D-line correspondences where the lines are the screw axes of the motors and the cameras.

We should note here that all other hand-eye calibration methods make use of the rotation angle and the pitch at least at the translation estimation step (3) which turns out in (30) to be unnecessary. Having shown that the problem is equivalent to the 3D-motion problem we already know from computer vision (Sabata & Aggarwal, 1991) that the minimum requirement are two non parallel lines. Hence, the minimal data for hand-eye calibration are two motions with non-parallel rotation axes.

## 6 Estimation of the hand-eye screw with SVD

Although we showed in the last section that only the vector part of the dual quaternions is relevant for the estimation of the unknown hand eye unit dual quaternion  $\tilde{\mathbf{q}}$  let us keep the same notation  $\tilde{\mathbf{a}}$  and  $\tilde{\mathbf{b}}$  for  $(0, \tilde{\mathbf{b}})$  and  $(0, \tilde{\mathbf{a}})$ , respectively.

We split the fundamental equation (28) into the non-dual and dual parts and we obtain

$$\begin{aligned}\mathbf{a} &= \mathbf{q}\mathbf{b}\bar{\mathbf{q}} \\ \mathbf{a}' &= \mathbf{q}\mathbf{b}\bar{\mathbf{q}}' + \mathbf{q}\mathbf{b}'\bar{\mathbf{q}} + \mathbf{q}'\mathbf{b}\bar{\mathbf{q}}.\end{aligned}$$

Multiplying on the right with  $\mathbf{q}$  and applying the identity

$$\bar{\mathbf{q}}\mathbf{q}' + \bar{\mathbf{q}}'\mathbf{q} = 0$$

in the first term of the right hand side of the first equation yields

$$\begin{aligned}\mathbf{a}\mathbf{q} &= \mathbf{q}\mathbf{b} \\ \mathbf{a}'\mathbf{q} &= -\mathbf{a}\mathbf{q}' + \mathbf{q}\mathbf{b}' + \mathbf{q}'\mathbf{b}\end{aligned}$$

which may be rewritten as

$$\begin{aligned}\mathbf{a}\mathbf{q} - \mathbf{q}\mathbf{b} &= 0 \\ (\mathbf{a}'\mathbf{q} - \mathbf{q}\mathbf{b}') + (\mathbf{a}\mathbf{q}' - \mathbf{q}'\mathbf{b}) &= 0.\end{aligned}$$

We keep in mind that from each of the two equations above the scalar part is redundant because they are equivalent to (30). Hence, we have in total six equations with eight unknowns which can be written in matrix form as follows. Let  $\mathbf{a} = (0, \tilde{\mathbf{a}})$  and  $\mathbf{a}' = (0, \tilde{\mathbf{a}}')$  as well as  $\mathbf{b} = (0, \tilde{\mathbf{b}})$  and  $\mathbf{b}' = (0, \tilde{\mathbf{b}}')$ . The quaternion equations above can then be written as a matrix vector equation

$$\begin{pmatrix} \tilde{\mathbf{a}} - \tilde{\mathbf{b}} & [\tilde{\mathbf{a}} + \tilde{\mathbf{b}}]_{\times} & \mathbf{0}_{3 \times 1} & \mathbf{0}_{3 \times 3} \\ \tilde{\mathbf{a}}' - \tilde{\mathbf{b}}' & [\tilde{\mathbf{a}}' + \tilde{\mathbf{b}}']_{\times} & \tilde{\mathbf{a}} - \tilde{\mathbf{b}} & [\tilde{\mathbf{a}} + \tilde{\mathbf{b}}]_{\times} \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ \mathbf{q}' \end{pmatrix} = 0 \quad (31)$$

where the matrix - we will call  $\mathbf{S}$  - is a  $6 \times 8$  matrix and the vector of unknowns  $(\mathbf{q}^T, \mathbf{q}'^T)$  is 8-dimensional. We denote with  $[\tilde{\mathbf{a}}]_{\times}$  the antisymmetric matrix corresponding to the cross-product with  $\tilde{\mathbf{a}}$ .

Recall that we have two constraints on the unknowns so that the result is a unit dual quaternion

$$\mathbf{q}^T \mathbf{q} = 1 \quad \text{and} \quad \mathbf{q}^T \mathbf{q}' = 0. \quad (32)$$

We could think that six equations plus two constraints would suffice, however, the vectors  $\vec{a}$  and  $\vec{b}$  are unit vectors and the vectors  $\vec{a}'$  and  $\vec{b}'$  are perpendicular to  $\vec{a}$  and  $\vec{b}$  so that two equations are redundant. This is nothing new, since it is well known that at least two lines are necessary so that 3D motion can be estimated from their correspondences (Sabata & Aggarwal, 1991). Thus, we need at least two motions of the hand-eye system in order to get two lines from the corresponding screws. (Chen, 1991) recognized also this fact and analyzed the uniqueness of the problem. He geometrically proved that even in the case of two parallel rotation axes we can compute all parameters up to the pitch.

Suppose now that  $n \geq 2$  motions are given. We construct the  $6n \times 8$  matrix

$$\mathbf{T} = \begin{pmatrix} \mathbf{S}_1^T & \mathbf{S}_2^T & \dots & \mathbf{S}_n^T \end{pmatrix}^T \quad (33)$$

which in the noise-free case has rank 6. Since in the noise-free case the equations arise from natural constraints the null-space contains at least the solution  $(\mathbf{q}, \mathbf{q}')$ . It is trivial to see that an additional orthogonal solution is  $(\mathbf{0}_{4 \times 1}, \mathbf{q})$ . Hence, the matrix is maximally of rank 6. If all axes  $\vec{b}$  are mutually parallel then the rank of the matrix is 5. The proof is quite lengthy and will not be given here, however, it is plausible that in this case a three-parameter family of solutions can not be constrained by the two conditions (32).

We compute the Singular Value Decomposition (SVD)  $\mathbf{T} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$  where  $\mathbf{\Sigma}$  is a diagonal matrix with the singular values, the columns of  $\mathbf{U}$  are the left singular vectors, and the columns of  $\mathbf{V}$  are the right singular vectors. If the rank is 6 then the last two right singular vectors  $\vec{v}_7$  and  $\vec{v}_8$  - corresponding to the two vanishing singular values - span the nullspace of  $\mathbf{T}$ . We write them as composed of two  $4 \times 1$  vectors  $\vec{v}_7^T = (\vec{u}_1^T, \vec{v}_1^T)$  and  $\vec{v}_8^T = (\vec{u}_2^T, \vec{v}_2^T)$ . A vector  $(\mathbf{q}^T, \mathbf{q}'^T)$  satisfying  $\mathbf{T}(\mathbf{q}^T, \mathbf{q}'^T)^T = 0$  must be a linear combination of  $\vec{v}_7$  and  $\vec{v}_8$ , hence

$$\begin{pmatrix} \mathbf{q} \\ \mathbf{q}' \end{pmatrix} = \lambda_1 \begin{pmatrix} \vec{u}_1 \\ \vec{v}_1 \end{pmatrix} + \lambda_2 \begin{pmatrix} \vec{u}_2 \\ \vec{v}_2 \end{pmatrix}.$$

The two degrees of freedom are fixed by the constraints (32) which imply two quadratic equations in  $\lambda_1$  and  $\lambda_2$ :

$$\lambda_1^2 \vec{u}_1^T \vec{u}_1 + 2\lambda_1 \lambda_2 \vec{u}_1^T \vec{u}_2 + \lambda_2^2 \vec{u}_2^T \vec{u}_2 = 1 \quad (34)$$

$$\lambda_1^2 \vec{u}_1^T \vec{v}_1 + \lambda_1 \lambda_2 (\vec{u}_1^T \vec{v}_2 + \vec{u}_2^T \vec{v}_1) + \lambda_2^2 \vec{u}_2^T \vec{v}_2 = 0 \quad (35)$$

Since  $\lambda_1$  and  $\lambda_2$  never both vanish, assume w.l.o.g. that  $\vec{u}_1^T \vec{v}_1 \neq 0$  so that  $\lambda_2 \neq 0$ . Setting  $s = \lambda_1/\lambda_2$  we first solve (35) obtaining two solutions for  $s$ . Inserting  $\lambda_1 = s\lambda_2$  in (34) yields

$$\lambda_2^2 (s^2 \vec{u}_1^T \vec{u}_1 + 2s \vec{u}_1^T \vec{u}_2 + \vec{u}_2^T \vec{u}_2) = 1 \quad (36)$$

which has two real solutions of opposite sign because it can be easily proved that the trinomial

$$(s^2 \vec{u}_1^T \vec{u}_1 + 2s \vec{u}_1^T \vec{u}_2 + \vec{u}_2^T \vec{u}_2)$$

is always positive or zero. Indeed, the second-order coefficient  $\vec{u}_1^T \vec{u}_1$  is positive and the discriminant  $4(\vec{u}_1^T \vec{u}_2)^2 - 4(\vec{u}_1^T \vec{u}_1)(\vec{u}_2^T \vec{u}_2)$  is always negative or equal zero due to the Schwartz inequality. We can easily prove that in the noise-free case the discriminant is equal to zero and an  $s$  exists which makes the left side of (36) vanish: If  $(\mathbf{q}^T, \mathbf{q}'^T)$  is a solution then  $(\mathbf{0}_{4 \times 1}, \mathbf{q})$  belongs to the kernel of the matrix  $\mathbf{T}$ . Hence,  $\lambda_1$  and  $\lambda_2$  exist so that  $\lambda_1 \vec{u}_1 + \lambda_2 \vec{u}_2 = 0$  that means,  $\vec{u}_1$  and  $\vec{u}_2$  are parallel and the discriminant  $4(\vec{u}_1^T \vec{u}_2)^2 - 4(\vec{u}_1^T \vec{u}_1)(\vec{u}_2^T \vec{u}_2)$  vanishes. Then, the double solution of

$s^2 \vec{u}_1^T \vec{u}_1 + 2s \vec{u}_1^T \vec{u}_2 + \vec{u}_2^T \vec{u}_2$  for  $s$  is  $-\|\vec{u}_1\|/\|\vec{u}_2\|$  which can be easily proved that it is also one of the solutions of (35) for  $\lambda_1 = s\lambda_2$  if  $\vec{u}_2 = \mu\vec{u}_1$ :

$$s^2 \vec{u}_1^T \vec{v}_1 + s \vec{u}_1^T (\vec{v}_2 + \mu \vec{v}_1) + \mu \vec{u}_1^T \vec{v}_2 = 0 \quad \Rightarrow \quad (s + \mu) \vec{u}_1^T (s \vec{v}_1 + \vec{v}_2) = 0.$$

In the presence of noise in order to avoid this solution for  $s$  resulting to  $(\mathbf{0}_{4 \times 1}, \mathbf{q})$  we always choose among the two  $s$ -solutions the one that gives the largest value for  $s^2 \vec{u}_1^T \vec{u}_1 + 2s \vec{u}_1^T \vec{u}_2 + \vec{u}_2^T \vec{u}_2$ .

The sign variation in the solution for  $\lambda_2$  in (36) is due to the sign invariance of the solution: Both  $(\mathbf{q}^T, \mathbf{q}'^T)$  and  $(-\mathbf{q}^T, -\mathbf{q}'^T)$  satisfy both the motion equations and the constraints.

The computation algorithm consists of the following steps:

1. Given  $n$  motor motions  $(\mathbf{b}_i, \mathbf{b}'_i)$  and corresponding camera motions  $(\mathbf{a}_i, \mathbf{a}'_i)$  check if the scalar parts are equal. Then extract the line directions and moments of the screw axes and construct the matrix  $\mathbf{T}$  in (33).
2. Compute the SVD of  $\mathbf{T}$  and check if only two singular values are almost equal to zero (due to noise we apply a threshold). Take the corresponding right singular vectors  $\vec{v}_7$  and  $\vec{v}_8$ .
3. Compute the coefficients of (35) and solve it finding two solutions for  $s$ .
4. For these two values of  $s$  compute  $s^2 \vec{u}_1^T \vec{u}_1 + 2s \vec{u}_1^T \vec{u}_2 + \vec{u}_2^T \vec{u}_2$  and choose the largest of them to compute  $\lambda_2$  and then  $\lambda_1$ .
5. The result is  $\lambda_1 \vec{v}_7 + \lambda_2 \vec{v}_8$ .

## 7 Experiments

In order to experimentally test the dual-quaternion method we performed simulations and a real experiment. To compare its performance and experimentally substantiate the theoretical differences we implemented two additional methods from the literature. The first one is similar to the one proposed by (Horaud & Dornaika, 1995) and is based like ours on the simultaneous computation of rotation and translation. Its representation consists of quaternions for the rotations and vectors for the translations. Equations (2) and (3) are combined additively into the following objective function

$$J(\mathbf{q}, \vec{t}_X) = \|\mathbf{a}\mathbf{q} - \mathbf{q}\mathbf{b}\|^2 + \|((\mathbf{R}_A - \mathbf{I})\vec{t}_x + \vec{t}_A)\mathbf{q} - \mathbf{q}\vec{t}_B\|^2 \quad (37)$$

to be minimized with respect to  $\mathbf{q}$  and  $\vec{t}_X$  subject to  $\|\mathbf{q}\|^2 = 1$ . After expressing the quaternion in spherical coordinates we apply the Levenberg-Marquardt minimization in its NETLIB Fortran implementation. This method makes use of all the information in the camera and motor motions including the angles and the pitches which are not used in the dual quaternion method. Like every iterative non-linear minimization it must be provided with starting values.

The second alternative method we applied was a two-step method as described in (Chou & Kamel, 1991). The first step solves for the rotation by minimizing

$$\|\mathbf{a}\mathbf{q} - \mathbf{q}\mathbf{b}\|^2 \quad \text{wrt } \mathbf{q} \quad \text{subject to} \quad \|\mathbf{q}\|^2 = 1$$

which can be reduced to an eigenvector problem. The second step solves the linear system (3) for the translation:

$$(\mathbf{R}_A - \mathbf{I})\vec{t}_X = \mathbf{R}_X \vec{t}_B - \vec{t}_A$$

In the following experiments and graphs we will denote our dual quaternion method with “DUAL”, the nonlinear simultaneous solution for rotation and translation with “NLIN”, and the separate solution with “SEPA”.

## 7.1 Synthetic experiments

The meaning of the synthetic experiments is to test the behavior of the above three methods under controllably varying factors. The simulation is conducted as follows: we establish  $N$  hand motions  $(\mathbf{R}_B, \vec{\mathbf{t}}_B)$  in a realistic set-up similar to the real experiment of the next section. We add Gaussian noise of relative standard deviation of 1% corresponding to the angle readings. We assume a hand-eye set up and compute the camera motions  $(\mathbf{R}_A, \vec{\mathbf{t}}_A)$  to which we add also Gaussian noise of varying standard deviation because this is the main source of errors due to the sensitive step of camera calibration. The noise is added as absolute value to the unit rotational quaternion and as relative value to the translation. For every noise setting each algorithm runs 1000 times and outputs the estimated rotation quaternion  $\hat{\mathbf{q}}$  and the estimated translation  $\hat{\vec{\mathbf{t}}}$  between gripper and camera. To qualify the results we take the RMS of the errors in the rotation unit quaternion  $\|\mathbf{q} - \hat{\mathbf{q}}\|$  and the RMS of the relative errors in the translation  $\|\vec{\mathbf{t}} - \hat{\vec{\mathbf{t}}}\|/\|\vec{\mathbf{t}}\|$ . These are customary error metrics used also in (Tsai & Lenz, 1989) and (Horaud & Dornaika, 1995). However, the reader should be aware of the fact that the Frobenius norm of the difference of the rotation matrices  $\|\mathbf{R} - \hat{\mathbf{R}}\|$  applied in these studies is much higher than the quaternionic error norm  $\|\mathbf{q} - \hat{\mathbf{q}}\|$  ( $2\sqrt{2}$  times larger if the axes are the same and the error is only in the angle).

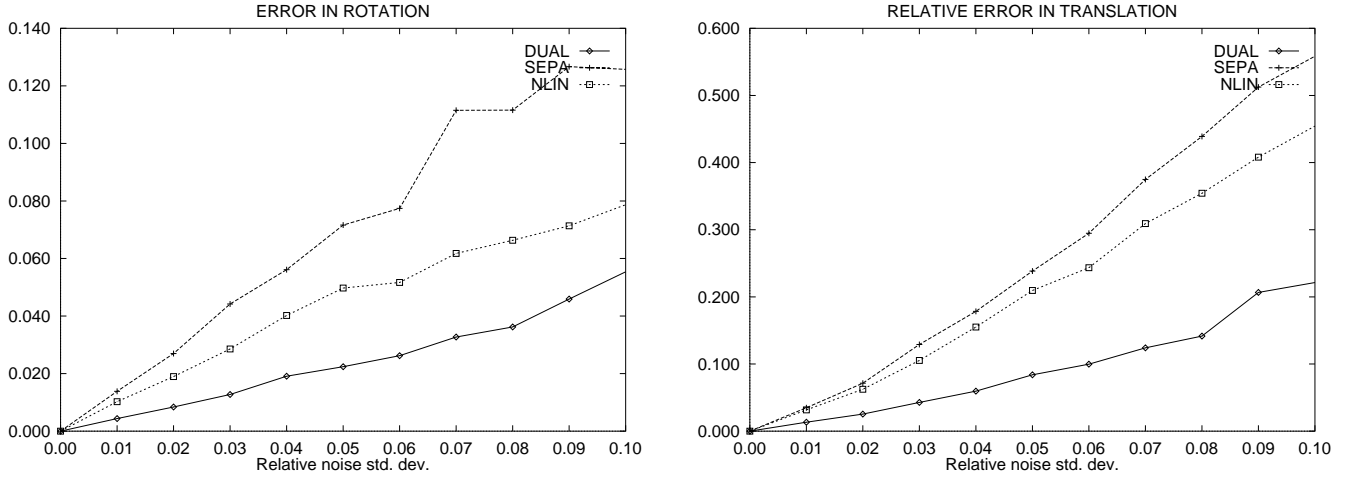

Figure 3: Behavior of the dual quaternion (DUAL), the nonlinear (NLIN) and the two-step algorithm (SEPA) in variation of noise. The RMS rotation error is shown on the left and on the right the RMS relative translation error.

In the first experiment we tested a standard configuration of 20 hand motions under different noise levels in the camera poses. In Fig. 3 we compare our algorithm (DUAL) with the nonlinear (NLIN) and the two-step (SEPA) algorithm. The dual-quaternion approach exhibits the best behavior followed by the nonlinear minimizer. The reason for this discrepancy is the convergence of the nonlinear method to local minima in a subset of the 1000 runs for each noise-level as well as the use of the angles and pitches in the nonlinear method.

In the second experiment we keep the noise level at 1% and we vary the number of motions from 2 to 20. We observe (Fig. 4) the same behavior in the simultaneous and the separate solutions in the case of just two motions. This is plausible since the number of unknowns is equal to the number of independent constraints in the pure rotational equations making it irrelevant whether we solve separately or not. For few motions the nonlinear algorithm does not converge properly. The dual quaternion algorithm is superior in multiple motions.

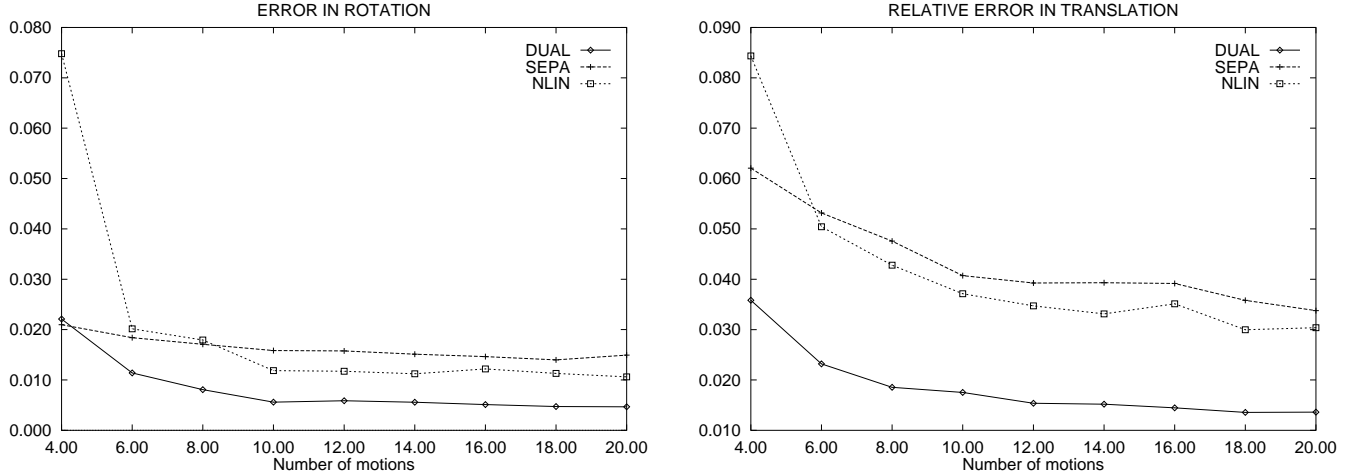

Figure 4: The RMS error in rotation (left) and the RMS relative error in translation (right) as a function of the number of hand and camera motions.

In the third experiment we varied the variance of the interstation rotation axes. This is according to (Tsai & Lenz, 1989) the most critical factor in the accuracy of hand-eye calibration. Again we keep the noise level at 1% and choose 20 rotation axes from a varying area on the unit sphere characterized by the polar angle. The x-axis in the plot of Fig. 5 represents the inverse of this area or the inverse of the axes direction variance. The behavior is explained by (Tsai & Lenz, 1989) for the two-step separate solution algorithm (SEPA): The smaller is the variance in the direction of rotation axes the higher is the estimation error. In the limiting case (not shown in the diagram) when all rotation axes are parallel the problem becomes singular. However, this is not an intrinsic property of the hand-eye calibration problem. We observe the striking phenomenon that the rotation error in both the nonlinear and the dual-quaternion approaches is invariant to this variation. This is not a surprise but a main advantage of the approaches solving simultaneously for rotation and translation: Rotation cannot be recovered from eq. (2) if all rotation axes are parallel. However, if both (2) and (3) are considered a unique solution for rotation exists but the translation still possesses one degree of freedom (Chen, 1991).

In all the simulations we observe the superior performance of the dual-quaternion algorithm. The non-linear minimizer could perform better if we could guarantee that it converges to the global minimum independent of the starting value. We experimentally showed that total ill-conditioning due to insufficient variation of the rotation axes is not an intrinsic property of the problem.

## 7.2 Real Experiments

The real experiments were conducted<sup>2</sup> with a Robosoft Pan-Tilt unit TO30 mounted on a controllable slider. The experimental configuration is illustrated in Fig. 6. The axes of the camera coordinate system  $(x_c, y_c, z_c)$  are parallel to the axes  $(x_m, y_m, z_m)$  of the motor coordinate system. There is a relative translation between the two coordinate systems in the  $y$ - and  $z$ -directions. To avoid introducing new terms we will mean the motor coordinate system when we will refer to hand or gripper in the following.

Since the ground-truth is unknown we are going to assess the performance of hand-eye calibration with two task-dependent methods: The first one - applied also in the classical paper by (Tsai

<sup>2</sup>The image and motor recordings are courtesy of Jean-Philippe Tarel, SYNTIM Project, INRIA Rocquencourt.

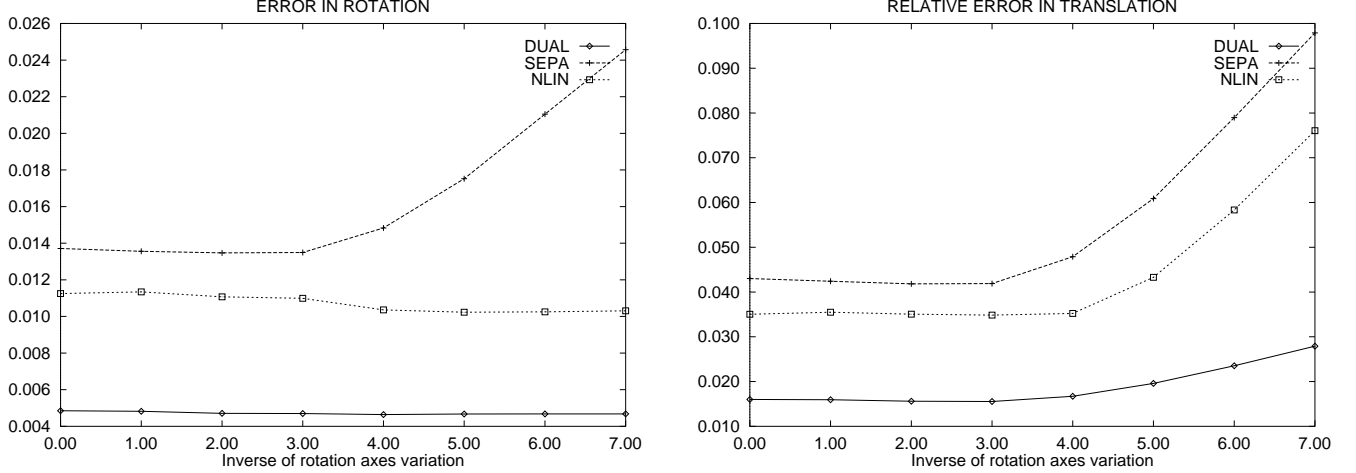

Figure 5: The RMS error in rotation (left) and the RMS relative error in translation (right) as a function of the inverse of the rotation axes variation. The horizontal axis is proportional to the inverse of an area on the unit-sphere inside where the rotation axes are distributed.

& Lenz, 1989) - is the ability to predict the camera pose by using only the motor motion data. This is very important for all tasks involving view planning or the opposite problem of gripper pose planning. The second assessment is reconstruction by motion stereo using one camera: The camera is calibrated only once and then moved to new positions where it is not calibrated again as it would be the case in using a left-right camera stereo system.

In the first assessment the camera was moved to 25 locations with different pan and tilt angles as well as different positions along the slider. The translation along the slider varied between 50 and 900 mm and the calibration object was at an approximate distance of 1000 mm. The camera was calibrated with the ellipse-based method (Tarel & Vzien, 1996) which includes the computation of the 3x4 projective matrix as well as its decomposition in intrinsic and extrinsic parameters due to (Faugeras & Toscani, 1986).

For  $N = 11..19$  stations we compute the hand-eye calibration by all three methods: the one-proposed here using dual-quaternions, the nonlinear simultaneous estimation, and the separate estimation of rotation and translation.

We extract the extrinsic parameters  $\mathbf{A}_i$  from every projective camera matrix (4) and use them together with the motor poses  $\mathbf{B}_i$  for the computation of the camera-gripper transformation  $\mathbf{X}$  from  $N$  positions. Then we predict the camera pose for the verification stations  $j = 20..25$  from the motor motion  $\mathbf{B}_j$  and the first camera pose  $\mathbf{A}_1$ :

$$\hat{\mathbf{A}}_j = \mathbf{X}^T \mathbf{B}_j^{-1} \mathbf{X}^{-1} \mathbf{A}_1.$$

We compare the predicted camera pose  $\hat{\mathbf{A}}_j$  with the camera pose  $\mathbf{A}_j$  extracted from camera calibration and average the errors over the 5 verification stations. The camera poses have an estimation error but we assume that this is much lower than the error in the predicted pose. This procedure is repeated for different number of frames  $N = 10..20$  used in the computation of the hand-eye matrix  $\mathbf{X}$ . The results for all three methods for varying  $N$  are shown in Fig. (7), the average absolute error for the rotation (left) and the average relative error for the translation (right). The number of verification stations was kept constant. The dual-quaternion method is slightly superior. Both simultaneous methods (dual-quaternion and nonlinear) perform better in the translation case

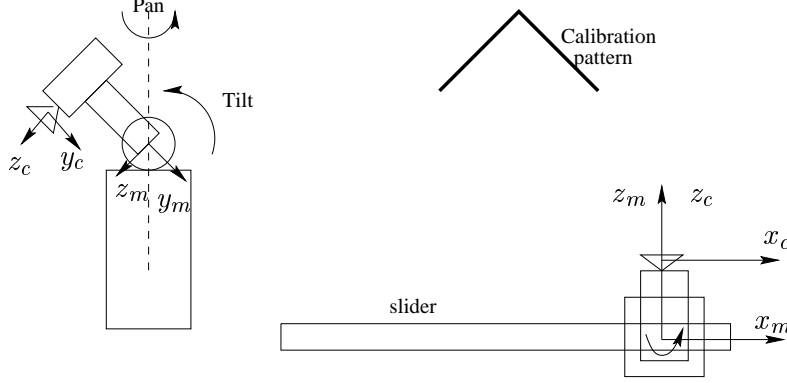

Figure 6: The pant-tilt from a top-view is shown on the left. The axes of the camera and the motor coordinate systems are parallel. The origins of the two coordinate systems differ by a  $y$ - and  $z$ -offset. On the right we show the experimental set-up with the slider, the pan-tilt head, and the calibration board.

where all methods show an error under 2%. We observe the expected decrease with the number of stations used, however, not as steep as expected because the variation of the interstation rotation axes is restricted as explained in the next paragraph.

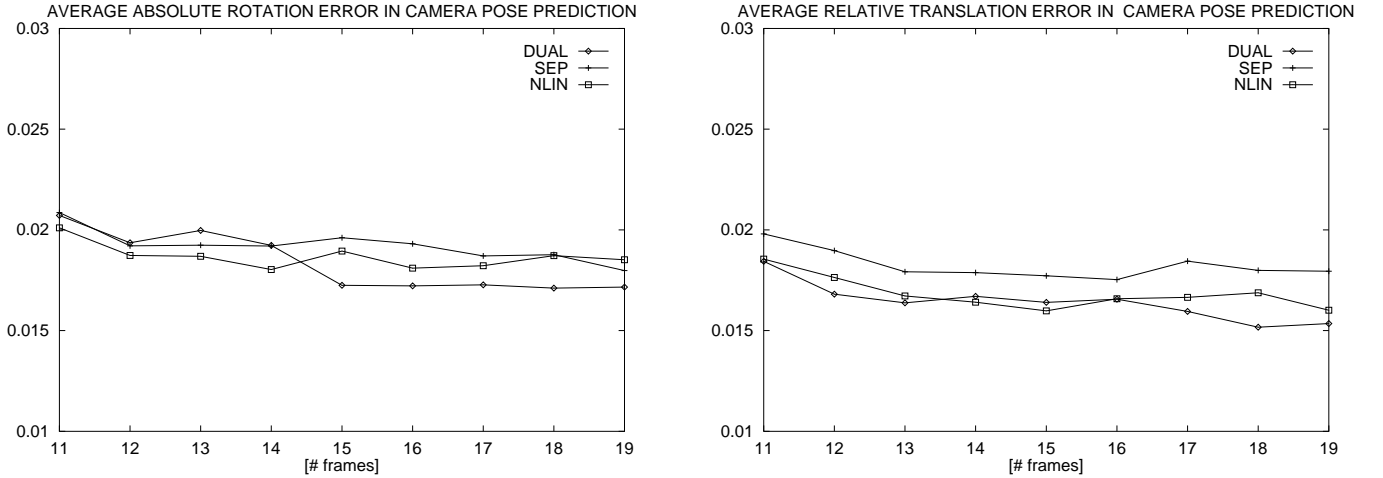

Figure 7: The discrepancy between predicted camera pose and the camera pose computed by camera calibration averaged over the five verification stations, the absolute error for the rotation matrices on the left and the relative error in the translation vectors on the right.

The error in the estimation of the hand-eye calibration depends on the errors in the camera poses and the motor recordings. Common sources of the observed error in the assessment of all methods are in the extrinsic pose extraction for the verification stations and the motor recordings in moving to these stations. Translation computation is very sensitive to noise due to the limited variation of the rotation axes of the interstation motions. This variation is constrained by the fact that the calibration target must always be inside the field of view.

To obtain a rough perception of the values of the hand-eye transformation itself the mapping computed with the dual quaternion methods using 20 stations was a rotation of 1.8 degrees about the  $x$ -axis and a relative translation  $(0, 125, -146)$  of the gripper with respect to the camera (cf.

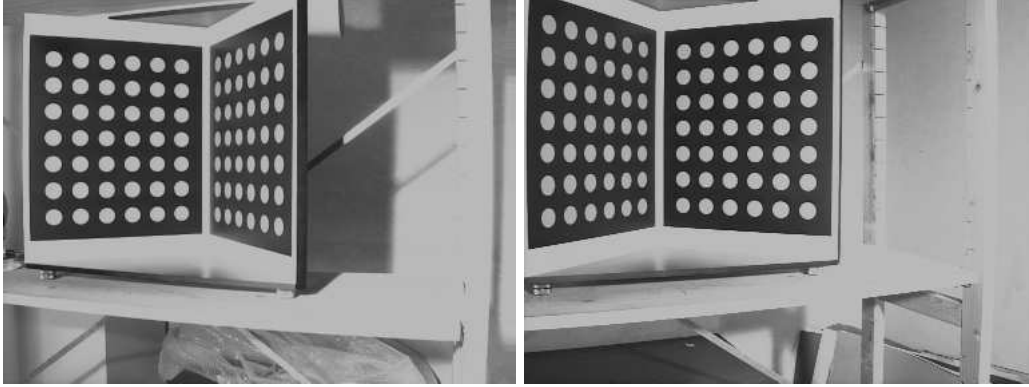

Figure 8: The 1st and the 22th image of the sequences of images used for stereo reconstruction.

Fig. 6).

The second experiment assesses the hand-eye calibration by one of each applications: motion stereo. Every time we have one camera and a controllable motion of a robot we can produce a polynocular stereo configuration only if we know the actuator-to-camera transformation. It is also a direct assessment since the assumed “ground-truth” are the positions of the world points in space which we know by designing the calibration object. In the first experiment the “ground-truth” was not veridical since the poses computed after calibration and decomposition were erroneous. We show in Fig. 8 two of the images used for the stereo reconstruction.

Stereo reconstruction with respect to a world-centered coordinate system necessitates the feature correspondences as well as two projective matrices  $\mathbf{M}_1$  and  $\mathbf{M}_2$  as defined in (4) of two cameras. The correspondences are given because we use the same calibration pattern as an object to reconstruct. We will apply all three methods described in the simulation section in two modes: The *extrinsic* mode and the *projective* mode.

In the *extrinsic* mode we use the extrinsic camera poses to compute the interstation camera motions  $\mathbf{A}$  and the result is the camera-hand transformation  $\mathbf{X}$ . Given only the first extrinsic matrix  $\mathbf{A}_1$  and the motor motion  $\mathbf{B}_2$  to a second position the projection matrices can be computed only if the intrinsic parameter matrix  $\mathbf{C}$  is known:

$$\mathbf{M}_2 = \mathbf{C} \mathbf{X} \mathbf{B}_2^{-1} \mathbf{X}^{-1} \mathbf{A}_1. \quad (38)$$

Given the correspondences in the first and the second image and the projection matrices  $\mathbf{M}_1$  from camera calibration and  $\mathbf{M}_2$  computed as above we perform classical stereo triangulation. The results of the extrinsic mode in all methods (denoted by DUAL, NLIN, and SEPA) are shown in Fig. 9 (left). In the same figure we show the reconstruction (CAM) using the second projection matrix from calibration as if we would calibrate in every position. Of course, the latter is superior to all motion stereo methods because no errors from the motor encodings or motor angle offsets or hand-eye calibration is involved. The same computed hand-eye transformation is used for all stations of the “second” camera. The curves show the absolute error for reconstruction between 1st and Nth frame where baseline is increasing with N. We observe the reconstruction error decay as the effective baseline increases. The non-regular behavior for specific stations is due to erroneous motor recordings.

In the *projective* mode, we avoid the decomposition in intrinsic and extrinsic parameters using the trick in eq. (5) (Horaud & Dornaika, 1995). Eq. (5) can be solved using dual quaternions in

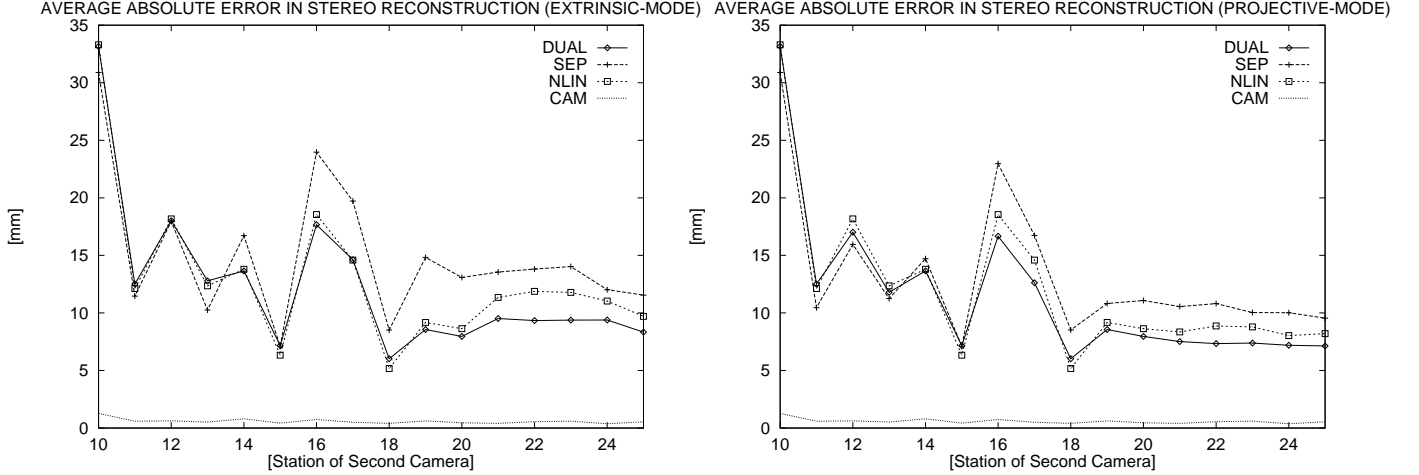

Figure 9: The average reconstruction error in [mm] as a function of the station which is proportional to the effective baseline (see also Fig. 6). The approximate depth of the points is about 100mm. The lowest curve (CAM) shows the error for conventional reconstruction using projection matrices computed at every frame. The curves show the average error of reconstruction using the second projection matrix computed from the *extrinsic* mode (left) and the *projective* mode (right) of hand-eye calibration. We denote by DUAL, NLIN, and SEPA the dual-quaternion method, the non-linear simultaneous, and the separate solution, respectively.

the same manner as in the first experiment. The result is the world to gripper transformation  $\mathbf{Y} = \mathbf{A}_1^{-1} \mathbf{X}$  at the first pose. The image to gripper transformation  $\mathbf{C}\mathbf{X}$  can be substituted by the image to world times world to gripper transformation as  $\mathbf{C}\mathbf{X} = \mathbf{M}_1 \mathbf{Y}$ . The necessary second projection matrix reads as follows

$$\mathbf{M}_2 = \mathbf{M}_1 \mathbf{Y} {}^l\mathbf{B}_2^{-1} \mathbf{Y}^{-1}. \quad (39)$$

We observe that the second projection matrix can be written in terms of the solution of the hand-eye problem without decomposing any matrix in intrinsics and extrinsics parameters. The results are shown in Fig. 9 (right) and are in most of the cases about 25% better than the results in the *extrinsic* mode. This error reduction is due to a more accurate hand-eye calibration using just projection matrices (6) and due to the fact that no decomposition is used in (39) either. The outliers are observed in the same stations which confirms our conjectures that they arise due to motor encoding errors in  ${}^l\mathbf{B}_2$ . In both modes we observe again the superiority of the methods solving simultaneously for rotation and translation.

## 8 Conclusion

Dual quaternions were long ago known in the kinematics as the algebraic representation of screws. We introduced in this paper this language to formalize the screw-approach to hand-eye calibration. We proved the fundamental fact that hand-eye calibration is a 3D-motion from 3D-lines problem. The invariance of the angle and the pitch is a straightforward result of the dual quaternion parameterization. This parameterization enabled us to establish a linear homogeneous system for the solution of all dual quaternion parameters. The computation of the nullspace with SVD and

the consideration of the constraints for the dual quaternion to be unit yields a simple algorithm avoiding non-linear steps.

We implemented two other methods, the first involving a non-linear minimization but solving simultaneously for rotation and translation, and the second solving linearly first for the rotation and then for the translation. We compared all three methods in simulations where we varied the noise level in the camera and motor poses. We also tested the effect of the number of calibration stations as well as the effect of the main conditioning factor which is the difference between the rotation axes directions. The superiority of the dual quaternion method lies not only in the simultaneous solution for rotation and translation but also in the use of the information which is just necessary for the hand-eye calibration problem. The angle and the pitch of the camera and the motor screws are irrelevant to the problem as also shown in the simulations. We applied all the methods in two variations in a real experiment of the active vision area. To achieve a better assessment of the methods we employed two different performance tests related to the tasks of controlled camera motion and stereo reconstruction, respectively. We elaborate further the dual quaternion approach for estimating hand-eye calibration in naturally singular configurations where conventional approaches are defeated. These include the calibration of cameras mounted on vehicles. Furthermore, the new representation open new ways for the solution of many computer vision problems involving line correspondences. For example, the extension of the algorithm presented here to the problem of registration of 3D line sets is trivial.

## Acknowledgments

Most of the work presented here was performed when the author was affiliated with the Cognitive Systems Group of the Kiel University. The author would like to thank Professor Hans-Hellmut Nagel for the common long discussions and calculations on dual numbers as well as the comments made by Professor Thomas Beth five years ago who both paved the ground for the results obtained here. The author gratefully appreciates the constructive comments and advice of Professor Gerald Sommer, the careful reading and the hospitality of Professor Andre Gagalowicz, and the discussions with Eduardo Bayro-Corrochano. The image and motor recordings in the first experiment are courtesy of Jean-Philippe Tarel, SYNTIM Project, INRIA Rocquencourt.
